Abstract. The PMP (Paraná Magmatic Province) is characterized by lava flows of the Early Cretaceous Serra Geral Formation which covers about 917 000 km², about 60 % of the surface of the Paraná Basin (Frank et al., 2009; Fig. 1). Three main petrographic types can be distinguished from macroscopic observation of these rocks. The most common type are basalts, presenting predominant intergranular texture and its variations, including subophitic, intersertal and hialophitic. The other two types of silicic rocks present massive and aphyric textures (Palmas type – ATP) and porphyritic textures (Chapécor type – ATC).

Macroscopic characteristics allowed easy separation in the field of these two members of the Serra Geral Formation and their geological mapping (Bellieni et al., 1983; Piccirillo et al., 1988). The Palmas and Chapécor rock types occur in association with basaltic flows that are more common near the top and bottom of these two lithostratigraphic units. Geological mapping also shows that the Palmas and Chapécor Members cover 63 000 km², in the states of Paraná, Santa Catarina and Rio Grande do Sul. The volume of the two members amounts to approximately 14 500 km³, which corresponds to 2.5 % of the total volume of the Serra Geral Formation (Nardy et al., 2002, 2008). Geochronological dating by ⁴₀Ar / ³⁹Ar shows that the age of volcanic rocks of the Serra Geral Formation ranges from 133.6 to 131.5 Ma in its northern sector, and from 134.6 to 134.1 Ma in the southern (Renne et al., 1992, 1996a; b; Turner et al., 1994; Ernest et al., 1999, 2002;
Fig. 1. Map of the Paraná Basin with the location of the acidic members of the Serra Geral Formation according to Nardy et al. (2008). Legend: 1 – pre-volcanic sedimentary rocks; 2 – basalts (the Serra Geral Formation); 3– silicic (a) Chapecó and (b) Palmas members (the Serra Geral Formation); 4 – sedimentary post-volcanic sequences (Bauru Basin); 5 – anticline structures; 6 – syncline structures; 7 – oceanic lineaments; 8 – continental lineaments.

Mincato et al., 2003; Thiede and Vasconcelos, 2010; Pinto et al., 2010). More recently, Janasi et al. (2011), using U/Pb ratios from baddeleyite/zircon crystals determined by isotope dilution thermal ionization mass spectrometry from rocks of the Chapecó Member, obtained an age of 134.3 ± 0.8 Ma, compatible with previous age determinations. However, ages obtained in the basaltic flows indicate the duration of the volcanism to be around 3 Ma, which is consistent with palaeomagnetic data presented by Ernesto and Marques (2004).

Thus far, the presence of sediments (sandstones of the Botucatu Formation) intercalated in the volcanic sequence was only reported in the lower basaltic pile. These consist of sand bodies presenting aeolian structures such as bypass surfaces, single dunes, sand-filled cracks and multi-dune ergs (Jerram and Stollhofen, 2002; Petry et al., 2007; Waichel et al., 2008), representing a desert environment that persisted during the voluminous initial phase of basaltic volcanism. In this work, the occurrence of sedimentation and development of associated peperites in the final stage of the PMP (Paraná Magmatic Province) volcanic event is presented. The sediments, predominantly sandy–silty, and unrelated to the Botucatu Formation, indicate a change in the environmental conditions in the Paraná Basin, and attest to the occurrence of significant periods of quiescence during the final stages of the magmatic activity.

2 Petrographic and geochemical aspects of silicic volcanic rocks

The Palmas-type silicic volcanic rocks (ATP) are characterized by light-gray to brownish-red color, hypohaline–holohaline, aphyric to micro-porphyritic textures and a striking salt-and-pepper aspect, with some holohaline units (pichstones) displaying black color, glassy luster and
prominent conchoidal fractures. However, due to its amorphous nature, the glass is easily altered and thus in most outcrops the rock is completely weathered, presenting a brownish color and (often resembling sedimentary deposits) dotted with abundant vesicles and quartz-filled amygdales up to 10 mm in length. The mineralogy is composed of microphenocrysts (granularity smaller than 0.2 mm) of plagioclase (labradorite) – which comprise up to 16% of the total volume of the rock – 11% of augite, 3% of pigeonite, 5% of magnetite and less than 1% of apatite. These crystals may exhibit rapid cooling structures (quenching), developing skeletal, lath and hollow shapes, or swallowtail terminations. The matrix reaches 63% of the rock volume on average, and is composed of dark-brown, slightly birefringent glass, characterized by a granophytic texture of abundant microlites, and alkali feldspar and quartz intergrowth that surrounds the crystal phases.

The Chapecó-type silicic volcanic rocks (ATC) are porphyritic, with an average of 24% of plagioclase phenocrysts up to 2 cm long, in a light-gray (when fresh) to brown (when weathered) aphanitic matrix. The mineralogy consists of euhedral andesine phenocrysts in a matrix composed of 45% of augite, 2.2% of pigeonite, 3.7% of magnetite, and 1.7% of apatite (average composition) surrounded by quartz and alkali feldspar fabric in felsitic, locally granophytic, arrangement (vitrophyric texture).

The chemical composition of the silicic volcanic rocks of the PMP, according to Nardy et al. (2008), show two main groups that may be observed in an R1 × R2 diagram (Fig. 2; De La Roche et al., 1980). The first one, the low-Ti suite, belongs to the tholeiitic field (tholeiitic basalts, andesi-basalts and andesites) associated with the Palmas-type silicic volcanic rocks, which belong to the rhyodacite and rhyolite fields. The second group, the high-Ti suite, is displaced towards the transitional field (transitiona basalt, lati-basalt and latites). The Chapecó-type silicic volcanic rocks belong to this group in the rhyodacite and quartz latite fields (Fig. 2). The bulk-rock representative compositions for both Palmas and Chapecó types are listed in Table 1.

According to Bellieni et al. (1984a) the chemistry of the volcanic rocks and their spatial distribution allow the Paraná Basin to be schematically subdivided into three main regions: (1) southern, encompassing the tholeiitic suite in the southern Uruguay River alignment; (2) northern, where tholeiitic-transitional rocks occur in the northern Piquiri River alignment; and (3) central, located between the Piquiri and Uruguay River alignments, where both rock types are present (Fig. 1). The spatial distribution of the tholeiitic – ATP and transitional-tholeiitic-ATC suites indicates that acidic volcanic rocks may have been derived from the associated basalts, or ATC melts are derived from tholeiitic-transitional basalts and ATP from tholeiitic basalts as suggested by Bellieni et al. (1986) and Garland et al. (1995).

![Fig. 2. R1 × R2 diagram (De La Roche et al., 1980). (A) Tholeiitic suite (Low-Ti basalts and ATP), and (B) tholeitic-transitional suite (High-Ti basalts and ATC).](image-url)

3 Stratigraphy

The 1600 m thick PMP volcanic sequence consists of up to 32 lava flows of predominantly basic to intermediate compositions (tholeiitic basalts, andesi-basalts and andesites), as well as felsic volcanic rocks (dacites, rhyodacites and rhyolites; Bellieni et al., 1984, 1986).

The base of the stratigraphic column is composed of a thick sequence of basic to intermediate flows that overlap the aeolian sandstones of the Botucatu Formation. The sandstones may also occur interlayered in the first hundred meters of the basaltic pile. The Palmas and Chapecó Members overlap the basalt flows. The Palmas Member is characterized by silicic volcanic bodies (ATP type) associated with a few basaltic lava flows and crops out from the central region of the basin southwards, where it may reach a thickness of 270 m. The Chapecó Member, composed of silicic volcanic rocks (ATC type), occurs in the northern and central regions of the Paraná Basin, the largest thickness, reaching 250 m, being present in the central region. This Member overlaps the basalts, but in the northern portion of the basin (Paranapanema River region – SP), it is found directly on the sandstones of the Botucatu Formation.

In the center of the basin the two silicic Members overlap, indicating that the Palmas Member is older than Chapecó, although ATP-type rocks may be found interlayered in the Chapecó Member.

The last pulses of PMP volcanism emplaced basalt flows that cover both the Palmas- and Chapecó-type rocks and become thicker towards the northern area of the basin.

3.1 Peperites and sedimentary deposit

The literature (Marques and Ernesto, 2004; Thiede and Vascconcellos, 2011) indicates that the PMP magmatism occurred quickly, during a time interval that did not exceed 3 Ma, and in a rather continuous way, based on a few occurrences of sedimentary intercalations or paleosoils within the volcanic sequence. However, recent field work has revealed the

presence of frequent sediment lenses and peperites in various stratigraphic levels within the silicic volcanic sequence.

Peperite is a genetic term used for rocks formed in situ by the interaction between hot magma (intrusive bodies, lava or pyroclastic flows) and coeval wet sediments (Fisher, 1960; Williams and Mc Birney, 1979; White et al., 2000; Skilling et al., 2002). Nonetheless, some authors (e.g., Jerram et al., 1999; Jerram and Stollhofen) have also described an interaction with dry sediments. Peperite is classified into two basic types according to the shape of its elements (Busby-Spera and White, 1987): blocky, in which the volcanic clasts present angular shapes and show a jigsaw-fit texture reflecting in situ quench fragmentation in a brittle state, and fluidal in which volcanic clasts present irregular, fluid (amoeboid), globular to undefined shapes, reflecting a ductile state during fragmentation, with the sediment often filling vesicles and being injected into cracks in the volcanic clasts/rocks, although more complex shapes may also be found (McPhie et al., 1993; Skilling et al., 2002).

Sedimentary deposits and peperites found in the Chapecó and Palmas members present a wide distribution in the Paraná Basin, as shown in Fig. 3, and are described below.

In the São Jerônimo da Serra (Paraná State) region, in the northern sector of the Paraná Basin, ATC-type rocks overlap a sandstone forming blocky peperite (Fig. 4). The blocky peperite is comprised of clastic dikes, which can be from a few centimeters to just over 1 m thick (Fig. 4a), and breccias, composed of matrix-supported angular to rounded volcanic blocks of variable size (Fig. 4b). The sandstone is poorly sorted with angular to rounded quartz grains (Fig. 4c and d),
and it was silicified by thermal metamorphism by the overlying volcanic material.

In the region of Mangueirinha and Palmas (Paraná State), in the center of the basin, both ATC- and ATP-type rocks crop out as either overlying basalts or overlapping each other. A sandstone layer was observed intercalated between ATC-type silicic body and an overlying basaltic lava flow. The base of the sediment is a breccia formed by vesicular ATC clasts set in a sandy matrix, implying some erosion degrees of the top of the volcanic body during sedimentation. In another location, an ATC-type silicic unit overlies a vesicular ATP-type silicic body, with a red clayey-silty sediment intercalated between the two units. The sediment was injected upwards into fractures in the overlying ATC unit forming peperite with both fluidal and blocky features (Fig. 5a and b), while in the underlying ATP unit, the sediment filled cooling cracks without any peperitic interaction (figure 5c and d). In a third exposure, a reddish-brown silty sediment, intercalated between two ATP volcanic units, formed peperite with blocky jointing morphology (Skilling et al., 2002), characterized by the injection of sediment into centimeter- to millimeter-spaced joints in the base of the overlying volcanic unit (Fig. 6).

In the southern region of the Paraná Basin (Rio Grande do Sul State), sediments and peperites were observed between some basaltic lower units and the overlying Palmas silicic sequence. In the Santa Maria region, blocky peperite was observed in the base of the lowermost silicic volcanic unit. The peperite displays a well-developed jigsaw-fit texture, and closely packed, blocky to cuneiform juvenile clast shapes of several sizes, separated by an orange-colored sedimentary material (Fig. 7). The sediment exhibits a high degree of baking (thermal metamorphism), and the juvenile clasts show intense devitrification, indicating very high temperature of the volcanic material interacting with the sediment.
Near the city of Venâncio Aires, a 10 m thick sedimentary layer underlies an ATP silicic volcanic unit. The sediment is a reddish-colored sandstone composed of sub-angular to rounded quartz grains (Fig. 8). The volcanic unit presents a well-developed horizontal jointed base and the contact with the sandstone is sharp, apparently lacking peperitic interaction (Fig. 8).

A road cut on the Soledade to Lajeado highway exposes a peperite in the base of a 25 m thick basaltic lava flow interlayered within the ATP silicic volcanic sequence. Volcanic clasts in the peperite are vesicular and display a variety of morphologies, from blocky to fluidal. The sediment is a red, poorly sorted sandstone, which partially fills vesicles in the volcanic clasts.

Eastward, in the area between Bento Gonçalves and Cambará do Sul (Rio Grande do Sul), all the observed peperites are interlayered within the silicic volcanic sequence and the sedimentary material becomes finer and predominantly silty. A peperite was observed in a quarry floor in Nova Petrópolis, near the city of Gramado, resulting from the interaction of sediment with a thin (∼1 m thick) amygdaloidal basalt interlayered in the silicic volcanic sequence. It displays blocky juvenile clasts with irregular shapes separated by orange to reddish, poorly sorted fine-grained sandstone. The sediment presents vesicles that probably resulted from volatilization of sediment water by heating (Fig. 9).

On the Rota do Sol highway, connecting Caxias do Sul to the coast, three peperite levels were observed interlayered in a sequence of black and glassy volcanic units of the Palmas Member. The stratigraphically lower two are similar and characterized by vesicular, pale to greenish and glassy volcanic clasts, presenting angular to rounded irregular shapes (Fig. 10). The sedimentary material is a brown, moderate to poorly sorted siltstone that also fills vesicles in volcanic clasts. The uppermost peperite presents juvenile volcanic clasts with a wide variety of morphologies, the fluidal shapes being more frequent (Fig. 11). The green and vesicular volcanic clasts are surrounded by a reddish-brown siltstone, which also fills vesicles and fractures in volcanic clasts (Fig. 11d). It is slightly coarser and more poorly sorted than the previous two sediments (Fig. 12), and many clasts of the stratigraphically lower peperite display perlitic fractures (Fig. 12c).

4 Discussion and concluding remarks

The PEMP (Paraná–Etendeka Magmatic Province) is considered one of the largest LIPs (large igneous provinces) of continental crust in the world, encompassing an area of nearly 1 million cubic kilometers (Bryan et al., 2010). Of total volume of the volcanic products, 95% are preserved in the South American continent, in the PMP. All volcanic material...
was erupted in a short period of time (∼3 million years) without significant interruption, as deduced from the scarcity of sediments interlayered within the volcanic sequence. In fact, and up to now, the only references to the presence of sediments interbedded within the volcanics corresponded to layers or lenses of sandstones (intertraps), a few centimeters to several meters thick, from the Botucatu Formation. These occur only in the base of the lava flow pile in both the African (Jerram et al., 1999, 2000; Jerram and Stollhofen, 2002) and South American continents (Petry et al., 2007; Waichel et al., 2008). Sandstone intertraps in rhyodacites in the Piraju–Ourinhos region (São Paulo State; Janasi et al., 2007; Luchetti, 2010), where the thick basaltic sequence is missing, were also known. However, until now, there were no reports of features indicating significant time breaks in the upper part of the PMP stratigraphic sequence.

New observations of the occurrence of sedimentary lenses and peperites, resulting from volcano-sedimentary interaction at the base and within the upper silicic sequences of the PMP are presented in this paper. Throughout the Paraná
Fig. 12. Photomicrographs of peperites from the Palmas volcanic sequence, along Rota do Sol highway: (a, b and d) volcanic glassy clasts (V) set in a brown siltstone matrix (S); (e) volcanic clast displaying concentric fractures – perlitic texture - common in the two lowermost peperites; (e and f) detail of the poorly sorted, slightly coarser siltstone from (d) (a, b, c, d and e – // polarizers; f – X polarizers; P = plagioclase).

Basin these were observed associated with silicic and basaltic units of the Palmas and Chapecó Members.

Some works on the PMP report peperites derived from the basalt-flow–sediment interaction (Petry et al., 2007; Waichel et al., 2007, 2008), the most common types found in worldwide volcanic sequences. Nevertheless, structures observed in this study reveal that this interaction also occurred between silicic extrusive bodies and wet sediment. These “silicic peperites” are mostly blocky, highlighting a more viscous magma (Dadd and Wagoner, 2002). However, they may also display fluidal features, which indicate less viscous melts, likely due to higher temperatures (> 1000°C; Piccirillo and Melfi, 1988).

The sediments display immature features, suggesting limited transport and, depending on the location, range from moderately to poorly sorted sandstones to siltstones. There was often lava–sediment interaction producing peperites or sediment deformation by the weight of overlying volcanic units. Evidence for the presence of wet and unconsolidated or poorly consolidated sediments is the variety of morphologies found, injections of sediment into fractures, vesicles in the juvenile clast filled by sediment and vesiculated sediment (Skilling et al., 2002).

Paleoenvironment climatic conditions at the time of the PMP volcanism were quite dry, since the Serra Geral Formation overlies the Botucatu Formation, described as a dry aeolian system (Sherer, 2000). Sandstone lenses up to 20 m thick interlayered in the first basalt lava flows (Jerram et al., 1999, 2000; Jerram and Stollhofen, 2002; Petry et al., 2007; Waichel et al., 2008) reveal that this system remained active during the magmatic event. However, new evidence of wet and locally silty sediment between basalt and silicic units and interlayered in the silicic units (end of the volcanic sequence) presented here reflect a paleoenvironmental change, from a dry climate in the beginning of the PMP volcanic activity to a more humid environment (fluvial–lacustrine) during the latest phases of the magmatism, as also evidenced by Waichel et al. (2007) in peperites found in some basalt units of the PMP in contact with lacustrine sediments. In the São Jerônimo da Serra region, the northern area of the basin, the change must have started before the volcanism. Furthermore, this seems to be common in this type of setting in which humid and dry aeolian systems may alternate over time due to climate changes (Assine et al., 2004).

The deposition of sediments must have taken place in depressed portions of the paleorelief (small valleys or depressions of the original volcanic morphology), and suggests a decrease in eruptive frequency towards the end of the volcanic activity, allowing time for the deposition of sedimentary material between individual volcanic events.

In conclusion, the PMP volcanism was not completely continuous, but presented significant pauses, mainly in the initial and terminal phases. On the other hand, the occurrence of sediments separating the top of the lower basaltic sequence and the beginning of the silicic extrusions may represent a pause in the volcanic activity that coincides with the compositional change in the magmatism of the Paraná Magmatic Province.
